## Content.

- Introduction.
- Main aspects of the code.
- How to run the code.
- Code.
- Sample input and output.

## Introduction.

The program allows the user to convert up to four currencies into one. This saves them the time of having to convert each currency individually. For example, if someone wanted to convert USD, EUR and GBP into CHF manually, they would have to convert each currency and then add them all together. In this program the user simply inputs the currencies, corresponding monetary quantities and final currency, and the program will return the sum of all the converted currencies. The program is also able to check the users gains/losses from previous currency exchanges. For example, if the user had converted USD to EUR on a specific date and wanted to know whether or not he would be better off having done that trade now, he would be able to check that. Lastly, the program can also give the user current spot rates.

All the exchange rates come from <https://exchangeratesapi.io/>, a currency API which uses the European Central Banks exchange rates which are updated on a daily basis. The program also uses the historical rates up until 2000 which are available from the same API.

## Main aspects of the code.

1. The loading of the data from the API. The program uses the requests package in order to obtain the data from a URL and stores them as a json file. This process is also used to obtain the historical rates, the code simply extends the URL by adding the date to it.
2. The while True: loop at the beginning of the code allows the user to repeat the process without having to manually click rerun. While true the program runs all the code and at the end has an if function where the user can either continue using the program or stop using it in which case the program ends.
3. The currency conversion formula is a bit more complicated than a standard conversion since all our exchange rates use USD as the base rate, so if a user wants the EUR/CHF rate, we need use the EUR/USD and CHF/USD

exchange rates. The two exchange rates are then divided in order to get the EUR/CHF rate.

4. To calculate the gains/losses from previous trade we do the same thing as above where we calculate the value of that exchange if it were done today. In addition, we repeat the process but use the historical rates to calculate the value of the trade on a different date. We then calculate the difference between the two values to see if the value was higher/lower if it were made today.

Note: in the older datasets the base rate is EUR and the data set does not attach a value to it (the value should be 1 since the rate would be EUR/EUR). Hence, there a few extra lines of code which attach the value 1 to the EUR/EUR. In the recent data sets the exchange rate of the base currency is included so we do not have this issue.

## How to run the code.

To run the code simply download the CurrencyConverterPython.py file from GitHub and run it using Spyder from the Anaconda-Navigator. To download the file, click on raw, the window should change so that all the code is shown on a white background, then right click and save the file. Downloading the Anaconda Navigator is straightforward, and it comes with the Spyder preinstalled. Then simply run Spyder and open the python file. You can also copy paste the code directly into Spyder.

## Code.
